Field Windbreaks for Row Crops

inter-row plantings of grain in white asparagus fields gave protection against wind erosion during tests on peat soil

Herbert B. Schultz and Alan B. Carlton

Inter-row planting as a practical management practice for the protection of white asparagus fields from wind erosion has been intensively studied since 1953. Such erosion is sometimes costly to the growers and is an important factor in peat dust storms.

Interplanting asparagus ridges with rows of fast growing small grains does not take land out of production, as do tree windbreaks; lath fences—snow fences—appear to be too expensive under the conditions. Furthermore, investigations have shown that inter-row plantings of grain are highly effective even against winds moving parallel to the row directions. However, inter-row planting is restricted to row crops that are sufficiently spaced to permit a strip of taller, protecting plants in each row space. Also, inter-row plantings can give wind protection for a few months only.

Fortunately, on the islands in the San Joaquin Delta, these two restrictions do not exist for one of its important crops, white asparagus. This crop is planted in ridges 7'-8' apart, providing space for one to three rows of grain between ridges. The need for protection against wind erosion is usually greatest during May and June, the months of optimum development for several varieties of barley and wheat.

A further factor supporting the preference for inter-row planting is the row orientation of many asparagus fields, which is unsuited for tree rows or snow fences with regard to the prevailing wind direction. At Terminous—the site of one of the special wind survey stations used in these studies—the prevailing wind direction is straight west. From there on, the oceanic air masses fan out according to the valley shape. At Ridgeline Tract—the second survey station—the oceanic flow is just beginning to turn away from its west direction and is mostly between west and west-northwest. In such conditions, tree windbreaks or fences should be oriented in a north-south direction, and so should be, preferably, the asparagus rows to prevent the tree windbreaks and snow fences from interfering with the numerous cultivations and daily tractor harvesting of the crop. However, even when a new asparagus

only one of magnesium nitrate, showed about 45% correction of the deficiency symptoms. Symptoms on the check trees had not improved.

The second experiment—in San Diego County—used only two applications of magnesium. The first spray was applied in the fall, on November 21, 1957, and the second on May 1, 1958. Single-tree plots were used, with the spray treatments and check replicated nine times. The fall application used five pounds of magnesium nitrate to 100 gallons of water and the spring application used 10 pounds to 100 gallons.

The second spray in this experiment was applied when the spring flush of growth was about two thirds expanded. Magnesium in leaf samples taken on May 22, 1958, three weeks after the spring spray, averaged 0.17% for the check and 0.23% for the sprayed trees. In each of the nine replications of the spray treatment, the concentration of magnesium in the leaves exceeded that of the check by more than 22%. The differences were highly significant.

The third experiment was a single application—in San Diego County, on May 1, 1958—using 10 pounds of magnesium nitrate per 100 gallons of water. The treatment was superimposed on a 3 x 2 x 2 = dolomite x potash x phosphate—factorial soil fertilizer experiment, replicated five times with two-tree plots. The plots in the factorial experiment that had received nitrogen, phosphorus, or potassium but no dolomite—that is, no magnesium—were split. One tree in each plot received a magnesium nitrate spray and the other was retained as a check. Additional plots, which had received a heavy mulch of steer manure every year since 1950, were split and sprayed in the same way. Leaf samples were gathered on May 22, 1958.

The trees of the factorial experiment had differential magnesium levels created in the leaves by past fertilizer treatments. Trees that had heavy applications of potash or manure in their prior fertilizer history had moderate to severe magnesium-deficiency symptoms. Regardless of previous fertilizer treatment, a single magnesium nitrate spray applied when the spring flush of growth was about two thirds expanded resulted in a substantial increase in magnesium concentration in leaves analyzed three weeks later.

When the spray was applied, deficiency symptoms had started to develop in leaves of the fall and winter flushes of growth. After two months, the sprayed trees had only about 40% as many leaves showing magnesium-deficiency symptoms as did the check trees. Apparently the sprays prevented further development of deficiency symptoms, but symptoms continued to develop in the check trees. The sprays did not correct symptoms that were present in the leaves at the time of spraying.

Magnesium nitrate spray at 10 pounds per 100 gallons of water applied to orange trees in San Diego County in August, 1958, gave little or no correction of the deficiency, suggesting that single summer applications are uncertain.

On some, but not all, light-textured citrus soils in California applications of Epsom salts—magnesium sulfate—have been effective, suggesting that a combination soil-spray program might be developed for such soils. No instance is known where applications of magnesium compounds to heavy-textured soils have corrected magnesium deficiency.

In earlier exploratory trials, foliage of orange trees was injured by magnesium nitrate at concentrations as low as 15 pounds per 100 gallons of water. Thus, 10 pounds of magnesium nitrate per 100 gallons approaches a maximum tolerable concentration. In Treatment 4, small quantities of zinc and manganese salts were combined with 10 pounds of magnesium nitrate per 100 gallons of water and no injury resulted from the treatment. However, as a precaution, magnesium nitrate sprays might be tested on a small number of trees before spraying an entire orchard.

Various wind profiles over asparagus ridges during dust storms.

Streamlines of oceanic air masses in the California valleys in summer. After Byers, 1930. The 6 dots show locations of California spot climate recorder stations on March and April. Stations shown in the northern half of the Central Valley served in the construction of the dotted lines: tentative extension, 1954.
