Postharvest survival of navel orangeworm assessed in pistachios

by Joel P. Siegel, L.P.S. (Bas) Kuenen, Bradley S. Higbee, Patricia Noble, Richard Gill, Glen Y. Yokota, Rodrigo Krugner and Kent M. Daane

Controlling navel orangeworm, a key pistachio pest, is problematic because the moth overwinters in “mummy” nuts. After harvest, there may be more than 30,000 pistachio nuts (mummies) left behind per acre. To provide better information for winter sanitation decisions, we investigated the number of available mummies and their levels of navel orangeworm infestation from winter through early summer in California pistachio orchards. Navel orangeworm mortality was highest from late December through mid-February, and was also higher on the ground than in trees. Mortality on the ground was highest when mummies were tilled or mowed with the groundcover than when nuts were left on the raised berm. Our data indicates that, in contrast to almonds, it is more productive to focus on clearing pistachios from the ground than on removing them from trees. However, winter sanitation procedures also should be augmented in order to destroy more overwintering navel orangeworm.

More than 95% of U.S. pistachio production occurs in California, primarily in the central and southern San Joaquin Valley (CPC 2007). California pistachio acreage has almost doubled over the past decade to more than 152,000 acres, and pistachios were the second-most valuable California nut crop in 2004 at $438 million, trailing only almonds (Boriss 2005).

Pistachios are harvested mechanically, first by shaking nuts from the tree and then collecting them in a catch apron. But unfortunately for the grower, the entire crop does not make it to market. Some of the nuts remain in the trees after shaking, and some harvested crop is lost due to spillage (Siegel et al. 2004). Our research focused on the nuts that remain on the ground and in the trees after harvest, known as “mummies.” They are costly not only because of their lost market potential but also because they are a resource for a key insect pest of pistachios: the navel orangeworm (Amyelois transitella [Walker]), a moth first described from specimens collected in Mexico (Wade 1961).

Despite its name, the navel orangeworm (NOW) is not a pest of navel oranges but rather a primary pest of California pistachios and almonds, as well as a serious pest of walnuts. Eggs are laid on the exterior of the nut or where the nuts attach to the stem. In some cases, if the hull has split and the kernel is exposed, eggs may be laid directly on the kernel. When the eggs hatch, the larvae crawl on the outside of the nut searching for a breach in the hull in order to gain entry and then burrow into the kernel. Navel orangeworm larvae cause direct damage by feeding on pistachio kernels, and indirect damage by increasing processing costs, reducing nut quality and facilitating aflatoxin contamination of nuts (Doster and Michailides 1994).

In both pistachios and almonds, there are multiple generations of navel orangeworm, and the population increases throughout the summer and early fall; consequently there are more moths in September than in July. The larvae and pupae that do not emerge from nuts spend the winter inside unharvested nuts, called “overwintering” (Caltagirone et al. 1968). Navel orangeworm develop intermittently in these mummies when the temperature exceeds 55°F (Engle and Barnes 1983), and oviposition can begin as early as mid-January on mummy almonds in Kern County. Although eggs laid this early are unlikely to develop successfully, those laid at the beginning of February can (Joel Siegel, unpublished data), and in most years emergence of adult moths to start the next generation is well under way throughout the San Joaquin Valley by mid-March. The later navel orangeworm generations, which emerge from August through September, are the most damaging to pistachios because pistachios become...
During the pistachio harvest, nuts that are not collected either fall on the ground or are left in the trees. These leftover “mummy” nuts can harbor navel orangeworm over the winter.

Infested after the hull breaks down, exposing the shell and/or kernel (Beede et al. 1984; Bentley et al. 2005). Because insecticides do not control the overwintering navel orangeworm population, it is suppressed by sanitation, a laborious process consisting of blowing fallen mummies from the berm (the area immediately surrounding the trunk, containing the irrigation lines) into the drive rows (the area between the tree rows), and then tilling these nuts into the soil. Growers may also shake mummies from the trees and then rake or blow the nuts into the drive rows to be tilled (UC IPM Online 2007).

While orchard sanitation successfully controls navel orangeworm in almonds (Zalom et al. 1984), its effectiveness in pistachios is variable. This is partly because pistachios cannot be readily shredded by tillage and may stick to the berm, and as a result cannot be blown into the drive rows for disking. As many as half of the nuts remain on the berm after blowing because moisture “glues” them to the soil (Siegel et al. 2004). Even when pistachios are successfully tilled into the soil, navel orangeworm larvae can emerge from nuts buried as deep as 6 inches (Bradley Higbee, unpublished data).

Even though unharvested pistachios provide the only available food and shelter for overwintering navel orangeworm populations, the fate of these mummy nuts and the overwintering navel orangeworm has not been extensively studied. We studied pistachio mummy and navel orangeworm prevalence from winter through early summer, using both normal sanitation and experimental ground-management practices.

**Prevalence of mummies and worms**

We conducted a series of three studies at S&J Ranch in Madera County from 2004 to 2007. During winter 2004–2005, a 40-acre pistachio block was selected after harvest and four rows were chosen at random. Within each row, samples of nuts were collected from the berm every three to four trees in December, February, April and June. In addition, two other rows were selected at random (0.25 miles per row) and all mummies were collected from the trees in December and February. A total of 175,350 nuts were collected in 2004–2005 from the ground and canopy. In the next study, conducted between April and June 2006, we assessed the prevalence of split nuts and collected 227,286 mummies from the berms in an 80-acre block, as described. In the final study, conducted between January and March 2007, navel orangeworm population density was assessed in a 160-acre pistachio block, and 359,087 mummies were collected from the berm, as described. Findings from all three studies are aggregated in the results presented here.

To calculate the prevalence of navel orangeworm, the mummies collected during all three studies were placed in

<table>
<thead>
<tr>
<th>Definitions: Processed pistachio nuts</th>
</tr>
</thead>
<tbody>
<tr>
<td>Upon arrival at the processor, pistachios fall into two broad categories. The first is nuts containing kernels, “filled nuts,” which in turn can be subdivided into split and unsplit nuts. About 75% of harvested nuts are filled nuts with split shells, based on data provided by Paramount Farming Company for 1998 to 2004 (&gt; 1.7 billion pounds field weight). The second category is un-filled nuts or “blanks,” which lack kernels. These nuts are removed during processing.</td>
</tr>
</tbody>
</table>
5-gallon buckets covered with netting, each containing about 550 mummies. The buckets were held at 80°F and checked periodically for adult emergence, which could be seen through the netting. All adults were removed, their numbers recorded, and the days elapsed from collection determined. For each sample date, about 10% to 30% of the nuts were removed from the buckets and sorted by hand to determine the percentage of split nuts and blanks. The total number of nuts collected was multiplied by the percentage of split nuts in order to determine the true number of nuts available to navel orangeworm. This is more accurate than calculating infestation by simply dividing the adults by the total number of nuts collected, because closed-shell and blank pistachios cannot be infested.

**Ground management practices**

For our ground management study, pistachio mummies were collected on Feb. 19, 2002, from an orchard in Madera County. Four lots of 100 mummies each were dissected to determine navel orangeworm prevalence, which averaged 35.5 ± 2.5% per lot, and the remaining mummies (4,800) were used in an experiment conducted in a pistachio research block at the University of California Kearney Agricultural Research and Education Center in Fresno County.

Ground management in this block consisted of a pre-emergent herbicide application on the berm to keep this section weed-free, but vegetation remained in the drive row. Four treatments were investigated: (1) placing mummies on the berm; (2) placing mummies in the middle of the drive rows and not mowing them; (3) placing mummies in the middle of the drive rows and then mowing them; and (4) placing mummies in the middle of the drive rows and then tilling them.

Treatments were set in a randomized block design with six replications. Each treatment plot was a 10.76-square-foot section of the berm or drive row that was isolated by cages (wooden frames 10.76 square feet at the base and 3.9 inches high) that were covered on top by organdy cloth immediately after treatment and left open underneath. Two hundred mummies (an estimated 71 navel orangeworm per plot based on the prior dissection) were placed in each plot, and the cages were checked weekly for adult emergence.

**Split mummies decrease**

Immediately after harvest, nuts remain on the ground due to spillage. In 2003 — in a separate study not described here — we dissected 9,300 split nuts immediately after harvest and determined that the prevalence of splits was 65.1% (Siegel et al. 2004). The percentage of split nuts observed on the berm in our three studies, 71% (table 1), was consistent with our previous work and also comparable to the average prevalence of split nuts in loads received by Paramount Farming Company between 1998 and 2004.

The recovery of split nuts decreases over time as more nuts fall from the tree, and by midwinter/early spring only 30.6% of the mummies collected in our three studies were split nuts. This occurs because more of the nuts remaining on the trees after harvest are blanks, which weigh less than filled nuts and are less likely to be shaken from the tree. This was confirmed in a previous study —
not described here — conducted in Kern County in 2003, when 20 trees were selected at random after the first shake and the remaining 280,500 nuts were removed, sorted and dissected by hand to determine the percentage of split nuts (38.1%). This is roughly comparable to the 30.6% split nuts recovered from the berm in our three studies between mid-winter/early spring.

The prevalence of split nuts continued to decline, and by mid-June 2005, only 13% of the mummies in our studies were split (table 2). In contrast, split nuts accounted for almost 43% of the mummies collected in the same orchard in June 2006, following a dry January and February (data not shown). The seasonal decline in split-nut recovery from the berm is due to a host of factors including germination, rotting, animal feeding and the continuous fall of blank nuts to the ground. Undoubtedly, differences in rainfall timing affect the rate of nut decomposition as well.

We could not assess seasonal changes in split nuts in the trees after February because by April there were few mummies remaining on the trees during the years studied. We obtained a rough estimate of the number of split mummies per acre by combining our data with previously published data on the average number of pistachios per tree. Pistachios are alternate bearing, which means that there is an “on” year of high nut production followed by an “off” year where production may drop as much as 60%. Goldhamer and Beede (2004) reported that mature trees in an “on” year produced an average of 12,000 nuts (74% filled, 26% blank) in Kings County during the 1991–1992 growing season. Today, a mature tree produces approximately 15,000 nuts in an “on” year, due to improved management practices. Based on the industry average of 135 trees per acre, during an “on” year an acre contains almost 2 million pistachios before harvest, of which approximately 1.44 million are filled (split and unsplit nuts). Assuming 90% harvest efficiency, the number of filled nuts left behind per acre after one shake is 144,000 per acre, most of which are split. If we assume that the maximum seasonal reduction in split nuts occurred in June 2005, an average orchard would contain 54,000 split nuts per acre (401 per tree) after harvest was concluded.

**Worm survival in mummies**

Navel orangeworm infestation in split nuts collected from the berm declined by 77% between December 2004 and February 2005, while there was no decline in navel orangeworm infestation of tree mummies during this same period (table 2). Because adult emergence is minimal during this period, we attribute the decline in navel orangeworm density on the ground to mortality. After February, however, adult emergence is a factor. Distinguishing between mortality and emigration in the field is a common problem in all insect mortality studies because the cause of the disappearance in the population is unknown, except for instances when adult emergence is minimal or cadavers are recovered (Siegel et al. 1987).

In our 2005–2006 study, which focused on ground mummies, the decline in navel orangeworm preva-
ience between Jan. 9 and Feb. 6, 2006, was 60%, roughly comparable to our previous finding. Daane et al. (2001) conducted a study in Madera County in which 39,933 mummies were collected between late January and mid-April, and also in early June. Navel orangeworm infestation declined 22% between January and February, and 74.6% between February and March. We noted declines of the same magnitude in our study during that same period in 2006 and 2007. However, mortality is confounded with emigration: We know that the numbers of navel orangeworm decreased in the samples based on our recovery of adults, but we do not know if this decrease was due to adults emerging before nuts were collected in February and April or whether navel orangeworm died inside the nuts and therefore did not emerge.

Combining our data on navel orangeworm prevalence for 2004–2005 with information on seasonal changes in the density of available mummies, we estimated changes in navel orangeworm density within an acre of pistachios (table 3). This analysis assumed that all filled nuts are split nuts, and ignored infested tree mummies and emigration of adults. Assuming a 95 tree-per-acre planting containing 91 female trees, we begin with an estimated 101,010 split nuts after harvest. This analysis also included the sex ratio of navel orangeworm as a factor, in order to determine if the population would increase in the next generation.

We cannot assume a 50:50 sex ratio in adults emerging from pistachio mummies because the actual male-to-female ratio was 57:43 in both field-collected samples and laboratory studies (3,844 adults examined, chi-square analysis, P < 0.0001). Consequently, although we estimated the April population to be 103 adults per acre, only 44 of these adults are female. If we assume that a female lays an average of 85 eggs in her lifetime (Wade 1961), there are 3,765 navel orangeworm eggs per acre to begin the first generation of the new crop year. This first generation of the new crop year is laid between February and early June, with peak oviposition occurring from late April into mid-May. The population will increase if more than 2.7% of these eggs develop into adults, or if mortality is less than 97.3%. The navel orangeworm population will increase further if survival in the succeeding generations — which are laid on new crop nuts — exceeds 2.0%, because the sex ratio of adults emerging from new crop pistachios is 50:50.

Navel orangeworm larvae are more likely to survive in mummies than pupae. In a 2005 Kern County experiment — not described here — researchers at the Paramount Farming Company dissected 176,625 pistachio mummies collected in February and 66,802 mummies collected in March (Bradley Higbee, unpublished data). In February, 10,692 larvae were collected and 84.3% of these larvae were still alive, but only 14.7% of the 835 pupae collected were alive. In March, larval survival decreased slightly to 81.8% (2,445 total) while pupal survival significantly increased to 67.6% (587 total) (2 × 2 contingency chi square, P < 0.0001, in both cases). The higher larval than pupal survival indicates that pupae are more susceptible to unidentified mortality factors between February and March.

**Controlling NOW in pistachios**

We found that ground mummies are an important source of navel orangeworm, and that mowing and diskng both the groundcover and nuts in row middles reduced navel orangeworm adult emergence. Moreover, burying the mummies kept females from laying eggs in them in the spring or early summer. In our experience, it is more economical to concentrate on removing or destroying mummies on the ground

![Fig. 1. Numbers of adult navel orangeworm emerging with four pistachio groundcover treatments. Treatment impact was determined using analysis of variance (P < 0.0001, df = 3,20, F = 21.761). Treatment separation, indicated by different letters above each bar, was determined using Fisher’s least square difference test (P < 0.05).](image-url)
To evaluate ground management practices, several hundred pistachio mummies were placed in each plot prior to treatment, and then covered with a wood frame to monitor the emergence of adult navel orangeworm.

Strategies for managing ground mummies include blowing them off the berm, and mowing and/or diskng them into the soil to inhibit navel orangeworm egg-laying.

than to shake them from pistachio trees, given the limited resources available to most growers for winter sanitation. However, consistently removing mummies from the berm remains a problem, and in these studies navel orangeworm–infested mummies had higher survival on the berm than those in the row middles.

Our emphasis on removing mummies from the ground for sanitation in pistachios is in sharp contrast to current recommendations for sanitation in almonds, where it is considered critically important to remove mummies from the trees (Zalom et al. 1984; UC IPM Online 2007). Undoubtedly, the importance of pistachio mummies remaining in the trees will continue to be debated, and further research is needed to resolve this issue. Research is also needed to identify the mortality factors responsible for the decline in winter navel orangeworm populations on the ground. It may be possible to augment pistachio sanitation with insecticide use in the fall (Siegel, Higbee, et al. 2006) as well as with entomopathogenic nematodes (Siegel, Lacey, et al. 2006), which have been previously tested in almonds (Agudelo-Silva et al. 1995). Ultimately, navel orangeworm control will be improved by increasing our understanding of the population dynamics of this pest and by integrating preharvest management practices with postharvest sanitation.
