Irrigated Pastures May Be Favorable to Livestock Parasites

M. A. Stewart

Certain internal parasites inhabit and reproduce in the bodies of sheep and cattle. The young, undeveloped parasites, excreted by the animal, find conditions in irrigated pastures well suited to their development.

Conditions Fostering Development

Irrigated pastures provide moist conditions and even temperatures at the base of plants where parasites thrive.

The plant growth protects the immature parasites from the drying effects of direct sunlight.

More animals per acre are carried on irrigated pastures than on non-irrigated lands, so the parasite population is higher.

Irrigated pastures are commonly used for young animals, which are more susceptible to parasites than are older ones, and consequently are greater carriers.

Control Measures

In spite of these dangers, irrigated pastures can be used to advantage if the operator will take certain routine measures to suppress parasites and prevent infection.

Coccidiosis. This disease is produced in sheep and cattle when the wall of the intestine is invaded by small one-celled parasites belonging to the genus *Eimeria*.

The most constant symptom is "bloody scours." Certain other conditions may produce similar symptoms but when such scours occur, coccidiosis should be suspected and a definite diagnosis should be made by a competent person.

Prevention is best assured by determining, as far as possible, that animals purchased come from "clean" ranches. When this is not known, the new animals, especially the young ones, should be quarantined for approximately two weeks before they are placed with other stock.

Under feed-yard conditions, infections in lambs may be prevented by mixing ground crude sulfur with the feed.

Seek Answers to Nitrogen Needs of Orchards in State

E. L. Proebsting

A high percentage of the peach orchards in California need nitrogen; a low percentage of the pears and prunes need it, and the other fruits and nuts fall in intermediate positions.

Properly used, a pound of actual nitrogen gives about the same response whether from manure or commercial fertilizer, and irrespective of whether it was given as a nitrate compound or as an ammonium compound. There might be secondary effects due to the form used, but generally, nitrogen from any standard source is satisfactory.

Time of Application

The time of application is a question involving more qualifications to the answer. In earlier studies, two situations were observed.

In one, an adequate amount of nitrogen was given annually to maintain a satisfactory level. Time of application was a minor factor after the first year.

In the other situation, encountered chiefly in shipping fruits where a moderate level is desired to encourage early maturity, timing is of much greater importance.

(Continued on page 3)

2,4D Valuable as Weed Killer When Properly Used But Can Be Detrimental To Soil and Crops if Mishandled

W. A. Harvey

Available in dry powder form and as liquid preparations the commercial 2,4-D is readily dissolved or emulsified in water to form a spray solution to be applied in sufficient volume to get distribution of the chemical to all the weeds.

Applications by airplane may require only 15 gallons

of concentrated solution per acre, while a field sprayer may apply 100 to 200 gallons per acre of a more dilute solution. The amount of chemical to use in this amount of solution will depend upon the weed problem, and will vary from three-quarters of a pound to three pounds of 2,4-D acid per acre.

(Above) Growth of semi-aquatic weeds along a ditch before application of 2,4-D. (Right) The effectiveness of proper application of 2,4-D may be seen in the dying and dead weeds.

Certain floating water weeds may be destroyed by a thorough spraying of the above-water portions of the plants.

Ordinarily the manufacturer's recommendations as to the amounts to use can be followed.

For controlling mustard and radish in grain fields about three-quarters of a pound of acid is required per acre and the cost for the chemical will be two to three dollars per acre.

For morning-glory control, where one and a half pounds per acre is the usual rate, the cost will be four to six dollars per acre. For some of the more resistant weeds, where three pounds may be required, the cost will be eight to twelve dollars per acre.

The cost of application usually is in the neighborhood of two dollars per acre.

Mode of Action

On most weeds the action of 2,4-D is much slower than that of other weed killers. Four to eight weeks may be required for the weeds to die down completely. In hot weather the effect is more rapid than in cool weather.

The first effect to be observed on sprayed plants is a twisting and bending of the stems and leaves. Some plants show a drying of the stem and leaves until the tops are completely dead. Others may remain green for several weeks, showing a swelling of the stems, with cracks or splits developing and callus tissue forming. Some of the woody plants change leaf color, becoming yellow or red as though it were autumn, before the leaves are dropped.

Seriously affected plants may have roots that are enlarged and spongy or are completely dead, several weeks after treatment.

Responses of Different Weeds

Of the perennial weeds tested, morning-glory (European bindweed) is apparently one of the easiest to kill. Hoary cress (white top) is somewhat more difficult but numerous kills of above 95 per cent with one spray have been obtained.

Several semi-aquatic weeds includ-

ing cattail, tule, bur-reed, and kelp can be killed by proper applications of 2,4-D even when they are rooted below the water surface. The addition of three gallons of diesel oil per 100 gallons of spray is of some value in obtaining a kill of these species, possibly because of better penetration of the waxy cuticle of the weed. The ester preparations appear to be especially effective on these same species.

Floating water weeds such as water hyacinth, yellow water-weed, and *Hydrocotyle* were easily destroyed by a thorough spraying of the above-water portions of the plants.

Plants that form rosettes are particularly susceptible in that stage. Other plants should be young and growing vigorously with a well developed leaf surface. Old mature plants respond slowly, or not at all. All plants are more easily killed in the small seedling stages provided the application can be made at that time.

Effect on Grasses

Grasses, in general, are much more resistant to 2,4-D than are broad-leaved plants. This difference makes it possible to use the chemical for the eradication of such lawn weeds as dandelions and plantain. Bluegrass and ryegrass are more resistant than the bent grasses or red top. The spray will kill clovers and black medic as well as the weeds.

Turfs, grass pastures and grass seed fields may be treated using one and one-quarter pounds of 2,4-D acid per acre in 100 or 200 gallons of water but should not be sprayed when the grasses are blooming.

Cereal grains are also more resistant than many of the grain field weeds, and 2,4-D is being widely used as a selective spray in grain fields. The usual rate has been one-half to three-quarters of a pound of 2,4-D acid per acre. With a ground rig this amount of acid is applied in 100 to 125 gallons of water. Some injury to

the grain has been noted when treatment was made on very young seedling grain but applications to grain that was four to six inches high have been without damage.

Apparently wild radish, star thistle, and mustard are readily killed by applications that ordinarily cause no damage to grain. Among the crops that have been successfully sprayed are oats, barley, and wheat. Milo and corn have been treated successfully using one to one and one-quarter pounds per acre.

Dusts containing 2,4-D will soon be available for treating grain fields. They must be used with care to prevent drift to other crops.

Applications by airplane of 15 gallons per acre of a solution containing about one and one-half pounds of 2,4-D were effective in controlling arrowhead lily, water plantain, some of the sedges, and other aquatic species infesting rice fields. Where the water was low at the time of spraying there was some damage to the rice but fields sprayed when the checks were full of water showed no injury.

Effect on Soil

Several instances of soil sterilization from the use of 2,4-D have been investigated. Broccoli, cabbage, sugar beets, tomatoes, beans and other crops have been damaged when put out in fields previously sprayed with 2,4-D. In several cases excessive amounts of the chemical had been used and in most cases the fields were dry from the time of application of the 2,4-D until immediately before planting the crop.

Tests indicate that the 2,4-D breaks down or leaches out of warm, moist soils within 30 to 60 days but may persist in cool, dry soils for six months or longer.

Flood irrigation following an application of 2,4-D would help to remove the residual chemical, particularly during the summer when the soil is warm. Winter rainfall is sufficient in many areas to remove the

Economic Outlook For The California Dairy Industry

Extract from forthcoming Experiment Station Circular No. 366, "The Dairy Situation in California, 1947."

James M. Tinley

The immediate and long-time outlook for the California dairy industry, though fraught with some dangers and difficulties, is distinctly favorable.

Population and Buying Power

It is estimated that California's population will reach 10 million before 1950.

Some decline in buying power from the 1946 level is to be expected. This will tend to reduce the per capita consumption for some dairy products. The total volume of consumption of dairy products, however, will not be greatly reduced because of the growth of population. Even in 1945, all consumer needs for such products as market milk and market cream were not fully met because of shortage of supply.

Production

It is probable that milk production will continue to expand for several years but at a slower rate than the population growth. California's deficit position as regards milk production will thus become more pronounced.

Utilization

A growing proportion of all milk fat sold by farmers will be used in market milk, market cream, and ice cream. Although the volume of production of evaporated and condensed milk and of powdered whole milk will probably decline below the peaks reached during the war years, these products will utilize a substantially greater proportion of California's output of milk fat than before the war.

It is unlikely that butter and cheese together will utilize much more than 10 per cent of all milk fat produced annually. California will have to import a growing proportion of its consumption needs of butter and cheese.

Prices

Beginning in 1947, a decline in prices of milk and dairy products is to be expected. On the other hand, most costs are likely to remain fairly rigid.

Dairymen would be well advised to give greater attention to reduction of indebtedness and increase in efficiency of operation.

James M. Tinley is Professor of Agricultural Economics, Agricultural Economist in the Experiment Station, and Agricultural Economist on the Giannini Foundation.

chemical and permit spring or summer seeding of most crops.

Precautions

In spite of the fact that 2,4-D has promise of being one of the most important chemicals in weed control, there are certain precautions in its use that should be observed.

1) Since the material is new and not thoroughly tested, it should be used with discretion and without the expectation of miracles from its use. The action is slow and a month or more may elapse before the tops are completely dead, and even a longer time before the roots disintegrate. In almost all cases, two sprays will be necessary to kill all the plants because some will be missed in the first spraying and new plants may come up from lateral roots not killed by the first spray. The sprayed area should be closely watched and any new growth or regrowth sprayed

(Continued on page 3)

Nutritional Value of Plants Not Lowered by Chemical Fertilization Research Reveals

Common foods grown with the aid of artificial chemical fertilizers have a nutritional quality comparable to that of foods produced in soils fertilized solely with manures or humus.

A twelve week experiment produced data indicating that plants grown in a chemical medium are

neither deficient in any dietary essentials nor toxic to animals feeding on them.

testing period, the guinea pigs in both groups showed good growth in length, excellent skeletal and muscular development, good condition of fur, clear eyes and all the other indications of nutritional well-being.

The growth date recorded indicated no superiority in the nutri-

Composite growth curves of guinea pigs on a sole diet of Astoria bent grass, grown in soil and in a nutrient solution.

neither deficient in any dietary essentials nor toxic to animals feeding on them.

Guinea Pigs Used As Subjects

Two groups of guinea pigs were used in a research study conducted by the Divisions of Plant Nutrition and Home Economics.

Each group was fed an exclusive diet of Astoria bent grass, selected by prior tests for palatability.

The first, or yardstick, group of guinea pigs was fed grass grown in soil with a known history of organic manuring.

The second group was fed grass grown in synthetic nutrient solution.

An accurate record of the growth curve of the animals served as the yardstick to measure the general dietetic adequacy in animal nutrition of plants grown without organic matter in a synthetic inorganic medium.

Growing the Feed in Soil

The soil plots on which the Astoria bent grass was grown by Prof. B. A. Madsen of the Agronomy Division consisted of fertile garden soil with a known fertilization history of sheep manure, alfalfa meal and barnyard manure, supplemented with commercial ammonium sulfate, calcium nitrate and ammonium phosphate.

Lead arsenate was added twice for insecticide purposes. The second application of the insecticide preceded the nutritional feeding experiment by three years.

Growing the Feed in Chemicals

Approximately 121 gallons of nutrient solution were used in tanks 120 inches long, 30 inches wide and eight inches deep. Forced aeration was given by two porous carbon tubes extending the length of each tank.

The nutrient solution was made with distilled water to which potassium nitrate, calcium nitrate, magnesium sulfate and ammonium phosphate were added.

A supplementary solution furnished boron, manganese, zinc, copper and molybdenum. Iron was added as the plants grew large.

The solution was analyzed from time to time and the chemical nutrients replenished as used.

Feeding Experiment

The grass was clipped twice a week and the clippings fed as the sole food to the animals directly or kept for several days in a refrigerator.

At the start of the feeding experiment, each guinea pig was given 100 grams of the grass daily. Later, the clippings were supplied for free-feeding and each animal often ate more than 300 grams daily.

Conclusions

At the end of the twelve week feed

ing quality of grass produced in soil over that produced in an artificial inorganic medium without soil. Such fluctuations in the growth as were observed are probably within the limits of variability among the animals.

The results of the feeding experiment gave no indication of any toxicity in the grass grown by the water method.

No evidence was found that plants grown in a chemical medium are deficient in any dietary essentials.

The experiment reported above was conducted co-operatively by Agnes Fay Morgan, Professor of Home Economics and Biochemist in the Experiment Station; Daniel I. Arnon, Associate Professor of Plant Nutrition and Associate Plant Physiologist in the Experiment Station; and Helen D. Simms, formerly research assistant in Home Economics.

2,4-D Valuable As Weed Killer But Can Be Detrimental

(Continued from page 1)

again as soon as it is large enough.

- 2) There is a definite soil sterilization from the use of 2,4-D as a weed-killer. How long the effect will last and how serious it will be under particular field conditions will depend on soil type, temperature, moisture and the succeeding crop.

- 3) Any sprayer or other equipment in which the chemical has been used should be thoroughly washed out before being used to spray other materials on field, orchard, or ornamental plants. Rinsing with a little cold water is not sufficient. The sprayer should be thoroughly washed out with several changes of water to which a little baking soda or washing soda has been added. The use of warm water is also advantageous.

- 4) In spraying lawns or other areas of weeds, it is important that no spray is allowed to reach nearby ornamental or crop plants. Even small amounts of the spray drifting from the nozzle may be sufficient to injure these plants, some of which are quite sensitive.

Commercial Products Available

At present there are available on the market over 60 commercial products containing 2,4-D which are registered with the Bureau of Chemistry, State Department of Agriculture.

W. A. Harvey is Associate in Botany and Associate in the Experiment Station, Davis.

The biology and the utilization of California browse plants are under study.

Seek Answers to Nitrogen Needs of Orchards

(Continued from page 1)

A question closely related to the one of timing is the effect of applications late in the growth cycle of the fruit on the resultant size. Experiments with cherries, peaches, apricots and prunes over a period of several years failed to show any benefit in larger fruit from such applications.

Rate of Use

Methods of determining the most satisfactory rate of use are under study at the present time.

The maximum rate that can be used without damage, and the most economical rate for a given set of conditions are points of information that are much more complicated than some of the questions studied earlier.

Research Continues

Considerations such as pruning method, temperature and light intensity in a district, soil depth and texture, and soil management influence the utilization of nitrogen.

As the work on nitrogen progresses, the problems become more complex and the desirability of developing shortcuts to the answers becomes greater. To find such quick methods becomes a major objective.

A program of field experimentation supplemented by laboratory and greenhouse research is being followed to provide more insight into fruit tree behavior and to form a basis for answers to growers' problems such as those indicated.

E. L. Proebsting, is Professor of Pomology and Pomologist in the Experiment Station, Davis.

Steamed Cull Limas Palatable Protein Source for Hogs

E. H. Hughes

Tons of cull and damaged beans are fed annually to livestock in the United States.

Most beans are cooked when fed to hogs because they are more palatable and are more completely utilized. The pig does not like raw beans because of the bitter taste, which disappears during the cooking process.

Steaming requires much less labor than boiling in open kettles and the final product is just as valuable.

Illustrating the method used in removing the beans from the cooker. Note the steam pipe disconnected.

Steaming has an additional value in that the beans may be processed, sacked and fed at any time of the year.

Experiment With Lima Beans

A quantity of cull lima beans was purchased for experimental purposes. The average percentage composition of several samples of cull lima beans was: moisture, 11.7; ash, 4.4; protein, 19.7; fat, 1.2; starch, sugar, etc., 57.8; and crude fiber, 5.0.

The pigs used in the experiment were good feeders with the initial weight of 52 pounds and were fed until they weighed about 200 pounds. They were kept on concrete floors, fed and watered in steel troughs and had access to inside and outside pens.

All mature beans are deficient in vitamin A and like barley, their lime content is low, therefore, in the experiment, four lots of pigs were fed steamed lima beans, rolled barley, tankage, alfalfa meal, salt and oyster shell flour.

In the first of two groups 15% lima

Control of Coddling Moth With DDT Spray on Apples and Pears Good in Investigational Work

Arthur D. Borden

During the past three seasons of investigational work with DDT for the control of coddling moth on apples and pears the results have been excellent.

It has proved so much more efficient than lead arsenate that its use during the coming season is generally recommended on apples and pears. There has been no apparent injury to fruit or foliage except when used in combinations with oil emulsions or when the DDT was dissolved in oil.

The outstanding advantage in the use of DDT is that good coddling moth control with this material has been obtained with the use of not over three applications of DDT where from five to seven applications of lead arsenate have been required.

As few as two thorough applications of DDT in the early season have practically stopped the flight and eliminated the damage of the first brood of coddling moth. A third application at a reduced dosage has stopped second-brood attacks on late varieties of fruit. This reduction in materials and in the cost of applying sprays, combined with the more efficient control of coddling moth, will mean much to the apple and pear growers in California.

Timing of DDT Applications

It has been found that it is not necessary to attempt to fill the calyx cups with DDT as has been the practice with lead arsenate. Instead of starting to spray with DDT when 50 to 75 per cent of the petals are off—as has been the practice for years with lead arsenate—the first application should not be made until 90 per cent or practically all of the petals have fallen. There has been some evidence that DDT sprayed in the blossoms has prevented the natural setting of fruit.

beans were fed but the tankage was varied from five per cent in lot one to 2.5% in lot two.

In the other pens 30% steamed limas were included and the tankage varied as in groups one and two.

The beans were fed in one trough and the rest of the ration fed in a separate one.

The average daily gains were similar for all lots and the feed required for 100 pounds of gain were not materially different.

Results

It appeared from this study that steamed limas could be fed successfully at either a 15% or a 30% level. It demonstrated further that 2.5% tankage in these rations was just as efficient as five per cent.

When the experiment was concluded, the hogs were slaughtered and examined. The carcasses were excellent and there was no apparent difference in the quality of the carcasses of the various lots.

Rations containing rolled barley, steamed beans, alfalfa meal, salt and oyster shell flour and a small amount of tankage resulted in economical gains, growth and fattening.

How the Beans Were Steamed

Enough beans for one day's feeding were weighed and placed in a clean garbage can, then a known amount of water was added, enough to cover the beans. They were allowed to soak over night.

In the morning they were placed in a round container which had a steam pipe connected through the center of the container into the true bottom. A false bottom filled with small holes was set about 10 inches above the true bottom, which permitted the steam to filter upwards through the beans.

With the cover of the container in place the beans were steamed for 20 minutes. The steam was then turned off and the beans allowed to self cook until the afternoon when they were removed.

The beans were allowed to cool before they were fed that evening and the next morning.

E. H. Hughes, is Professor of Animal Husbandry and Animal Husbandman in the Experiment Station, Davis.

The second application should be started 15 to 17 days after the beginning of the first spray. The third application, if required on early harvested varieties, should be applied at least three weeks before harvest. On late varieties of pears and apples this application should be made in late June or early in July at the first appearance of the second brood of moths.

Materials and Dosages Recommended

The fifty per cent wettable DDT powder, as used during the past season, is apparently the safest and the most economical formulation to use on pears and apples. The addition of a small amount of powdered spreader such as four ounces of Multifilm or eight ounces of DDT Depositor plus

Fully grown coddling moth larva in a pear.

from one pint to one quart of kerosene will increase the deposit of DDT on the fruit.

No spreader containing spray oil or any type of spray oil emulsion should be used with DDT as leaf injury and even defoliation may occur.

The addition of lead arsenate to the following DDT spray formulas is not necessary but if for any reason it is desired to use lead arsenate either in a split program or in combination with DDT the 1946 spray program may be followed.

Small amounts of so-called soluble copper compounds, bordeaux mixture, or sulfur may be added to the early DDT sprays for the control of scab, mildew, and the prevention of fire-blight if necessary.

In the first two applications—delayed calyx and first cover spray—the following dosages are recommended:

50 per cent DDT wettable powder.....	1½ to 2* lbs.
Dry spreader or deposit builder.....	4 to 8 oz.
Kerosene.....	1 pt. to 1 qt.
Water.....	100 gals.
In the late cover spray:	
50 per cent DDT wettable powder.....	1 to 1½* lbs.
Dry spreader or deposit builder.....	4 to 8 oz.
Water.....	100 gals.

*The higher dosages to be used where infestations are serious.

Cautions

In this late spray the addition of a miticide such as DN-111 or xanthone to control the brown mite, two-spotted mite, and European red mite may be added to the DDT formula. Dosages of these miticides should follow the manufacturer's recommendations. Kerosene or oil emulsions should not be used with DN-111. Kerosene—up to one quart per 100 gallons of spray—may be added to the DDT-xanthone combination, but no oil emulsions should be used with xanthone. Oil emulsions for the control of mites should not be combined with DDT or used within three weeks of the last DDT application.

On apples the woolly apple aphid may become a serious pest following the use of DDT. Timely applications of an aphicide, such as nicotine or

(Continued on page 4)
